Abstract—XML technologies have undoubtedly become a standard for data representation and manipulation and are widely used in various spheres of human activities. Thus it is inevitable to propose and implement efficient techniques for managing and processing XML data.

A natural alternative is to exploit tools and functions offered by relational database systems. Unfortunately this approach has many objectors who point out especially its inefficiency caused by structural differences between XML data and relations. On the other hand, relational databases have long theoretical and practical history and represent a mature and reliable technology, i.e. they can offer properties that no native XML database can offer yet. On this account we believe that the database-based XML processing should be further studied and enhanced.

In this paper we study techniques which enable to improve XML processing based on relational databases, so-called adaptive or flexible mapping methods. First of all, we discuss reasons why these techniques are important and promising. Secondly, we provide an overview of existing approaches, we classify their main features, and sum up the most important findings and characteristics. Finally, we discuss possible improvements and corresponding key problems.

Index Terms—XML-to-relational mapping, state of the art, adaptability, relational databases.

I. INTRODUCTION

Without any doubt the eXtensible Markup Language (XML) [1] is currently one of the most popular formats for data representation. It is well-defined, easy-to-use, and involves various recommendations such as languages for structural specification, transformation, querying, updating, etc. The wide popularity naturally invoked an enormous endeavor to propose faster and more efficient methods and tools for managing and processing XML data. Soon it was possible to distinguish several different directions based on various storage strategies. The four most popular ones are:

- methods which store XML data in a file system,
- methods which store and process XML data using an (object-)relational database system,
- methods which exploit a pure object-oriented approach, and
- native methods that use special indices, numbering schemes [2], and/or data structures [3] proposed or suitable particularly for tree structure of XML data.

Naturally, each of these approaches has both keen advocates and objectors who emphasize its particular advantages or disadvantages. The situation is not good especially for file system-based and pure object-oriented methods. The former ones suffer from inability of querying without any additional preprocessing of the data, whereas the latter approach fails especially in finding a corresponding efficient and comprehensive tool. Expectably, the highest-performance techniques are the native ones since they are proposed particularly for XML processing and do not need to artificially adapt existing structures to a new purpose. Nevertheless, the most practically used ones are undoubtedly methods which exploit features of (object-) relational databases. The reason is that such databases are still regarded as universal and powerful data processing tools and in relation to their long theoretical and practical history they can guarantee a reasonable level of reliability and efficiency. Contrary to native methods it is not necessary to start “from scratch” but we can rely on a mature and verified technology, i.e. properties that no native XML database can offer yet. On this account we believe that these methods and especially their possible improvements should be studied and further enhanced.

Under a closer investigation the database-based methods can be further classified and analyzed [4] [5]. We usually distinguish:

- generic methods, i.e. methods which store XML data regardless the existence of corresponding XML schema (e.g. [6] [7] [8]),
- schema-driven methods, i.e. methods based on structural information from existing schema of XML documents (e.g. [9] [10]), and
- user-defined methods, i.e. methods which leave all the storage decisions in hands of future users (e.g. [11] [12]).

1In the rest of the paper the term “database” represents an (object-)relational database.
Techniques of the first mentioned type usually view an XML document as a general directed tree with several types of nodes. We can further distinguish generic techniques which purely store components of the tree and their mutual relationship [6] [7] and techniques which store additional structural information, usually using a kind of a numbering schema [8]. The schema enables to speed up certain types of queries but usually at the cost of inefficient data updates.

The fact that generic techniques do not exploit possibly existing XML schemes can be regarded as both advantage and disadvantage. On one hand they do not depend on its existence but, on the other hand, they cannot exploit the additional structural or type information. But together with the finding that a significant portion of real XML documents (52% [13] of randomly crawled or 7.4% [14] of semi-automatically collected) have no schema at all, they seem to be the most practical choice.

By contrast, schema-driven methods have contradictory advantages and disadvantages. Considering the disadvantages the situation is even worse for methods which are based particularly on XML Schema [15] [16] definitions (XSDs) and focus on their special features [10]. As it is expectable, XSDs are used even less (only for 0.09% [13] of randomly crawled or 38% [14] of semi-automatically collected XML documents) and even if they are used, they often (in 85% of cases [17]) define so-called local tree grammars [18], i.e. languages that can be defined using Document Type Definition (DTD) [1] language as well. The most exploited “non-DTD” features are usually simple types [17] whose lack in DTD is well-known and crucial but for XML data processing have only a side optimization effect.

Another problem of purely schema-driven methods is that information XML schemes provide is not satisfactory. Analysis of both XML documents and XML schemes together [14] shows that XML schemes are too general in comparison to their instances. Excessive examples can be recursion or "*" operator which allow theoretically infinitely deep or wide XML documents, i.e. the information they carry is from this point of view useless. Naturally XML schemes also cannot provide any information about, e.g., retrieval frequency of an element or an attribute or the way they are retrieved. Thus not only XML schemes but also corresponding XML documents and XML queries need to be taken into account to get overall notion of the demanded XML-processing application.

The last mentioned type of approach, i.e. the user-defined one, is a bit different. It does not involve methods for automatic database storage but rather tools for specification of the target database schema and required XML-to-relational mapping. Though it seems to be a marginal approach, it is commonly offered by almost all known (object-)relational database systems [19] as a feature that enables users to define what suits them most instead of being restricted by features and especially disadvantages of a particular technique. Nevertheless, the disadvantage is evident — it assumes that the user is skilled in both database and XML technologies. And particularly for complex applications the task to propose a good database schema is not easy.

As we can observe, advantages of all three approaches are closely related to the particular situation. Thus it seems to be advisable to propose a method which is able to exploit the current situation and information or at least to comfort to them. Naturally this idea is not new. If we analyze database-based methods more deeply, we can distinguish so-called flexible or adaptive methods (e.g. [20] [21] [22] [23] [24] [25]). They take into account a given sample set of XML data, XML queries, and/or various user-given information which specify the future usage and adapt the resulting database schema to them. It is not surprising that such techniques have better performance results than the fixed ones (e.g. [6] [7] [9] [10]), i.e. methods which use pre-defined set of mapping rules and heuristics regardless the intended future use. Nevertheless, the adaptive techniques have also one great disadvantage — the fact that the target database schema is adapted only once, at the beginning. Thus if the expected usage strategy changes, the efficiency of such techniques can be even worse than in corresponding fixed case. Consequently the adaptability needs to be dynamic.

The idea to adapt a technique to a sample set of data is naturally closely related to analyses of typical features and properties of real XML documents [14]. If we combine these two ideas, we can assume that a method which focuses especially on these typical XML features will be also more efficient than the general one. A similar observation is already widely exploited for example in techniques which represent XML documents as a set of points in multidimensional space [26] [27]. Efficiency of such techniques depends strongly on the depth of XML documents or the number of distinct paths — naturally both the values should be as small as possible. Fortunately XML analyses confirm that real XML documents are surprisingly shallow — the average depth does not exceed 10 levels [13] [14].

Considering all the mentioned points, the presumption that an adaptive enhancing of XML-processing methods focusing on given or typical situations seems to be a promising type of improvement. Thus in this paper we study adaptive techniques from various points of view. We provide an overview of existing approaches, we classify them and their main features, and we sum up the most important findings and characteristics. Finally, we discuss possible improvements and corresponding key problems as well as so far unconcerned issues. This analysis should serve as a good starting point for proposal of an enhancing of existing adaptive methods as well as of an unprecedented approach. For this purpose we also mention and discuss (in our opinion) possible improvements of weak points of existing methods and solutions to the most of the stated open problems.

The rest of the paper is structured as follows: The second section contains a brief introduction to formalism used throughout the paper. Section 3 describes and classifies the existing related works, both practical and theoretical and Section 4 sums up their main characteristics. Section 5 discusses possible ways of improvement of the recent approaches and finally, the sixth section provides conclusions.

---

Data collected with interference of a human operator who removes damaged, artificial, too simple, and/or otherwise useless XML data.
II. DEFINITIONS AND FORMALISM

Before we begin to describe and classify adaptive methods, we state several basic terms used in the rest of the text.

An XML document is usually viewed as a directed labelled tree with several types of nodes whose edges represent relationships among them. Side structures, such as entities, comments, CDATA sections, processing instructions, etc., are without loss of generality omitted.

Definition 1: An XML document is a directed labelled tree $T = (V, E, \Sigma_E, \Sigma_A, \Gamma, lab, r)$, where
- $V$ is a finite set of nodes,
- $E \subseteq V \times V$ is a set of edges,
- $\Sigma_E$ is a finite set of element names,
- $\Sigma_A$ is a finite set of attribute names,
- $\Gamma$ is a finite set of text values,
- $lab : V \rightarrow \Sigma_E \cup \Sigma_A \cup \Gamma$ is a surjective function which assigns a label to each $v \in V$, whereas $v$ is an element if $lab(v) \in \Sigma_E$, an attribute if $lab(v) \in \Sigma_A$, or a text value if $lab(v) \in \Gamma$, and
- $r$ is the root node of the tree.

A schema of an XML document is usually described using DTD or XML Schema language. Both the languages use a similar approach and describe the allowed structure of an element using its content model. An XML document is valid against a schema if each element matches its content model. (We will state the definitions for DTDs only. For XSDs similar against a schema if each element matches its content model.

To simplify the XML-to-relational mapping process an XML schema is often transformed into a graph representation. Probably the first occurrence of this representation, so-called DTD graph, can be found in [9]. There are also various other types of graph representation of an XML schema, nevertheless the analyzed techniques use the following or a similar one. If necessary, we mention the slight differences later in the text.

Definition 5: A schema graph of a schema $S = (\Sigma'_E, \Sigma'_A, \Delta, s)$ is a directed, labelled graph $G = (V, E, lab')$, where
- $V$ is a finite set of nodes,
- $E \subseteq V \times V$ is a set of edges,
- $lab' : V \rightarrow \Sigma'_E \cup \Sigma'_A \cup \{\text{"\}"}, \{\text{"+"}, \text{"*"}, \text{"?"}, \text{"\,\"\}"\}\cup \{\text{pcdata}\}$ is a surjective function which assigns a label to $\forall v \in V$, and
- $s$ is the root node of the graph.

The core idea of XML-to-relational mapping methods is to decompose a given schema graph into fragments, which are mapped to corresponding relations.

Definition 6: A fragment $f$ of a schema graph $G$ is each its connected subgraph.

Definition 7: A decomposition of a schema graph $G$ is a set of its fragments $\{f_1, ..., f_n\}$, where $\forall v \in V$ is a member of at least one fragment.

III. EXISTING APPROACHES AND THEIR CLASSIFICATION

Up to now only a few papers have focused on a proposal of a database-based XML-processing method which is able to adapt the target database schema to given information or typical situations. We distinguish two main directions — cost-driven and user-driven. (We wittingly use the term “user-driven” to distinguish the approach from the “user-defined” one.)

Techniques of the former group can choose the most efficient XML-to-relational storage strategy automatically. They usually evaluate a subset of possible mappings and choose the best one according to the given sample of XML data, query workload, etc. The main advantage is expressed by the adverb “automatically”, i.e. without necessary or undesirable user interference.

By contrast, techniques of the latter group also support several storage strategies but the final decision is left in hands of users. We distinguish these techniques from the user-defined ones since their approach is slightly different: By default they offer a fixed mapping. But users can influence the mapping process by annotating fragments of the input XML schema (which should not be mapped by default) with demanded storage strategies. In other words the user is enabled to improve the fixed strategy. Similarly to the user-defined techniques this approach also assumes a skilled user but, on the other hand, most of the work is done by the system itself and the user is expected to help the mapping process, not to perform it.

In the following subsections we briefly describe the found existing methods of the two approaches and we further classify their features.

A. Cost-Driven Techniques

As mentioned above, cost-driven techniques can choose the best storage strategy for a particular application automatically, without any interference of a user. In other words the user can
influence the mapping process only through the provided XML schema, set of sample XML documents or data statistics, set of XML queries and eventually their weights, etc.

Each of the techniques can be characterized by the following five features:

- an initial XML schema \( S_{init} \);
- a set of XML schema transformations \( T = \{ t_1, t_2, ..., t_n \} \), where \( \forall i : t_i \) transforms a given schema \( S \) into a schema \( S_i \);
- a fixed XML-to-relational mapping function \( f_{map} \) which transforms a given XML schema \( S \) into a relational schema \( R \);
- a set of sample data \( D_{sample} \) characterizing the future application, which usually consists of
  - a set of XML documents \( \{ d_1, d_2, ..., d_k \} \) valid against \( S_{init} \), and
  - a set of XML queries \( \{ q_1, q_2, ..., q_l \} \) over \( S_{init} \), eventually with corresponding weights \( \{ w_1, w_2, ..., w_l \} \), \( \forall i : w_i \in \langle 0, 1 \rangle \), and
- a cost function \( f_{cost} \) which evaluates the cost of the given relational schema \( R \) with regard to the set \( D_{sample} \).

The required result is an optimal relational schema \( R_{opt} \), i.e. a schema, where \( f_{cost}(R_{opt}, D_{sample}) \) is minimal.

It is important to mention that though the set of transformations \( T \) is always finite, they often generate a possibly infinite set of XML schemes. It is caused by the fact that particular transformations have usually various parameters or infinite set of XML schemes. It is caused by the fact that if XML documents are mostly semi-structured, a "classical" decomposition of unstructured or semi-structured XML parts into relations (e.g. [9]) leads to inefficient query processing caused by plenty of inevitable join operations. The algorithm exploits the idea of storing well structured parts into relations and semi-structured parts in a more natural way – using so-called XML data type, which supports path queries and XML-aware full-text operations. The fixed mapping for structured parts is similar to the classical Hybrid algorithm [9], whereas, in addition, it exploits \( NF^2 \)-relations using constructs such as set-of, tuple-of, and list-of.

The main concern of the method is to identify the structured and semi-structured parts. The process consist of the following steps:

1) Hybrid Object-Relational Mapping: One of the first attempts of a cost-driven adaptive approach is a method called Hybrid object-relational mapping [20]. It is based on the fact that if XML documents are mostly semi-structured, a "classical" decomposition of unstructured or semi-structured XML parts into relations (e.g. [9]) leads to inefficient query processing caused by plenty of inevitable join operations. The algorithm exploits the idea of storing well structured parts into relations and semi-structured parts in a more natural way – using so-called XML data type, which supports path queries and XML-aware full-text operations. The fixed mapping for structured parts is similar to the classical Hybrid algorithm [9], whereas, in addition, it exploits \( NF^2 \)-relations using constructs such as set-of, tuple-of, and list-of.

The main concern of the method is to identify the structured and semi-structured parts. The process consist of the following steps:

1. A schema graph \( G_1 = (V_1, E_1, \text{label}_1) \) is built for a given DTD.
2. For \( \forall v \in V_1 \) a measure of significance \( \omega_v \) (see below) is determined.
3. Each \( v \in V_1 \) which satisfies the following conditions is identified:
   - a) \( v \) is not a leaf node.
   - b) For \( v \) and \( \forall v \) its descendant \( v_i : \omega_v < \omega_{LOD} \) and \( \omega_v < \omega_{LOD} \), where \( \omega_{LOD} \) is a required level of detail of the resulting schema.
   - c) \( v \) does not have a parent node which would satisfy the conditions too.
4. Each fragment \( f \subseteq G_1 \) which consists of a previously identified node \( v \) and its descendants is replaced with an attribute node having the XML data type, resulting in a schema graph \( G_2 \).
5. \( G_2 \) is mapped to a relational schema using a fixed mapping strategy.

The measure of significance \( \omega_v \) of a node \( v \) is defined as

\[
\omega_v = \frac{1}{2} \omega_{S_v} + \frac{1}{4} \omega_{D_v} + \frac{1}{4} \omega_{Q_v}
\]  

\[
\omega_{D_v} = \frac{\text{card}(D_v)}{\text{card}(D)}
\]  

\[
\omega_{Q_v} = \frac{\text{card}(Q_v)}{\text{card}(Q)}
\]

where

```python
Algorithm 1 Naive Search Algorithm
Input: \( S_{init}, T, f_{map}, D_{sample}, f_{cost} \)
Output: \( R_{opt} \)
1: \( S \leftarrow \{ S_{init} \} \)
2: while \( \exists t \in T, s \in S : t(s) \notin S \) do
3: \( S \leftarrow S \cup \{ t(s) \} \)
4: end while
5: cost_opt \leftarrow \infty
6: for all \( s \in S \) do
7: \( R_{tmp} \leftarrow f_{map}(s) \)
8: \( \text{cost}_{tmp} \leftarrow f_{cost}(R_{tmp}, D_{sample}) \)
9: if \( \text{cost}_{tmp} < \text{cost}_{opt} \) then
10: \( R_{opt} \leftarrow R_{tmp} \)
11: \( \text{cost}_{opt} \leftarrow \text{cost}_{tmp} \)
12: end if
13: end for
14: return \( R_{opt} \)
```
of the amount of possible XML-to-relational mappings. On the other hand, the optimization is too restrictive in terms of (sub)optimum (lines 13 – 19).

As we can see, the algorithm optimizes the naive approach mainly in the following points:

- The schema graph is preprocessed, i.e. $\omega_{v}$ is determined for $\forall v \in V_1$.
- The set of transformations $T$ is a singleton.
- The transformation is performed if the current node satisfies the above mentioned conditions a) – c).

As it is obvious, the preprocessing ensures that the complexity of the search algorithm is given by $K_1 \ast \text{card}(V_1) + K_2 \ast \text{card}(E_1)$, where $K_1, K_2 \in \mathbb{N}$. On the other hand, the optimization is too restrictive in terms of the amount of possible XML-to-relational mappings.

2) LegoDB Mapping: Another example of adaptive cost-driven methods, was proposed and implemented for LegoDB system [21] and later enhanced and extended into FlexMap framework [29]. The algorithm optimizes the naive approach using a simple greedy strategy as depicted in Algorithm 2.

Algorithm 2 Greedy Search Algorithm

Input: $S_{\text{init}}, T, f_{\text{map}}, D_{\text{sample}}, f_{\text{cost}}$
Output: $R_{\text{opt}}$

1: $S_{\text{opt}} \leftarrow S_{\text{init}}$
2: $R_{\text{opt}} \leftarrow f_{\text{map}}(S_{\text{opt}})$
3: $\text{cost}_{\text{opt}} \leftarrow f_{\text{cost}}(R_{\text{opt}}, D_{\text{sample}})$
4: loop
5: $\text{cost}_{\text{min}} \leftarrow \infty$
6: for all $t \in T$ do
7: $\text{cost}_{t} \leftarrow f_{\text{cost}}(f_{\text{map}}(t(S_{\text{opt}})), D_{\text{sample}})$
8: if $\text{cost}_{t} < \text{cost}_{\text{min}}$ then
9: $t_{\text{min}} \leftarrow t$
10: $\text{cost}_{\text{min}} \leftarrow \text{cost}_{t}$
11: end if
12: end for
13: if $\text{cost}_{\text{min}} < \text{cost}_{\text{opt}}$ then
14: $S_{\text{opt}} \leftarrow t(S_{\text{opt}})$
15: $R_{\text{opt}} \leftarrow f_{\text{map}}(S_{\text{opt}})$
16: $\text{cost}_{\text{opt}} \leftarrow f_{\text{cost}}(R_{\text{opt}}, D_{\text{sample}})$
17: else
18: break;
19: end if
20: end loop
21: return $R_{\text{opt}}$

The main differences in comparison with the naive approach are the choice of the least expensive transformation at each iteration (lines 5 – 12) and the termination of searching if there exists no transformation $t \in T$ that can reduce the current (sub)optimum (lines 13 – 19).

The set $T$ of XML-to-XML transformations involves the following XSD modifications:

- **Inlining and outlining** – mutually inverse operations which enable to store columns of a subelement or attribute either in a parent table or in a separate table
- **Splitting and merging elements** – mutually inverse operations which enable to store columns of a shared element either in a common table or in separate tables, each for a particular sharer.
- **Associativity and commutativity** – operations which enable to group different elements into one table
- **Union distribution and factorization** – mutually inverse operations which enable to separate out components of a union using equation $(a, (b \cup c)) = ((a, b) \cup (a, c))$
- **Splitting and merging repetitions** – exploitation of equation $(a^+) = (a, a^*)$
- **Simplifying unions** – exploitation of equation $(a|b) \subseteq (a?, b?)$

Note that except for commutativity and simplifying unions the transformations generate equivalent schema in terms of equivalence of sets of document instances. Commutativity does not retain the order of the schema, whereas simplifying unions generates a more general schema, i.e. a schema with larger set of document instances. (Unfortunately only a subset of the mentioned transformations – namely inlining and outlining – was implemented and experimentally tested by the FlexMap system.)

The fixed mapping again uses a strategy similar to the Hybrid algorithm but it is applied locally on each fragment of the schema. The fragments are specified by the transformation rules stated by the search algorithm. For example elements determined to be outlined are not inlined though a “traditional” Hybrid algorithm would do so.

The process of evaluating $f_{\text{cost}}$ is significantly optimized. A naive approach would require:

- construction of a particular relational schema,
- loading sample XML data into the relations, and
- cost analysis of the resulting relational structures.

The LegoDB evaluation exploits an XML Schema-aware statistics framework StatiX [30] which analyzes the structure of a given XSD and XML documents and computes their statistical summary. The XML statistics are then “mapped” to relational statistics regarding the fixed XML-to-relational mapping and together with sample query workload used as an input for a classical relational optimizer which estimates the resulting cost. Thus no relational schema has to be constructed. Furthermore, as the statistics are respectively updated at each XML-to-XML transformation, the XML documents need to be processed only once.

3) An Adjustable and Adaptable Method (AAM): The following method, which is also based on the idea of searching a space of possible mappings, is presented in [22] as an Adjustable and adaptable method (AAM). In this case the authors adapt the given problem to features of genetic algorithms. This

4An element with multiple parent elements in the schema – see [9].
5A parent element involving the shared element.
is also the first paper that mentions that the problem of finding a relational schema $R$ for a given set of XML documents and queries $D_{\text{sample}}$, s.t. $f_{\text{cost}}(R, D_{\text{sample}})$ is minimal, is NP-hard in the size of the data.

The set $T$ of XML-to-XML transformations consists of inlining and outlining of subelements. For the purpose of the genetic algorithm each transformed schema is represented using a bit string, where each bit corresponds to an edge of the schema graph and it is set to

- 1 if the element the edge points to is stored into a separate table, or
- 0 if the element the edge points to is stored into parent table.

The bits set to 1 represent “borders” among fragments, whereas each fragment is stored into one table corresponding to so-called Universal table [6]. The extreme instances correspond to “one table for the whole schema” (in case of 00...0 bit string) resulting in many null values and “one table per each element” (in case of 11...1 bit string) resulting in many join operations.

Similarly to the previous strategy the genetic algorithm chooses only the best possible continuation at each iteration. The algorithm consists of the following steps:

1) The initial population $P_0$ (i.e. the set of schema bit strings) is generated randomly.
2) The following steps are repeated until terminating conditions are met:
   a) Each member of the current population $P_i$ is evaluated and only the best representatives are selected for further production.
   b) The next generation $P_{i+1}$ is produced by genetic operators crossover, mutation, and propagate.

The algorithm terminates either after certain number of transformations or if a good-enough schema is achieved.

The cost function $f_{\text{cost}}(R, D_{\text{sample}})$ is expressed as:

$$f_{\text{cost}}(R, D_{\text{sample}}) = f_M(R, D_{\text{sample}}) + f_Q(R, D_{\text{sample}}) \tag{4}$$

$$f_M(R, D_{\text{sample}}) = \sum_{i=1}^q C_i \times R_i \tag{5}$$

$$f_Q(R, D_{\text{sample}}) = \sum_{i=1}^m S_i \times P_{S_i} + \sum_{k=1}^n J_k \times P_{J_k} \tag{6}$$

where

- $f_M(R, D_{\text{sample}})$ is a space-cost function, where $C_l$ is number of columns and $R_l$ is number of rows in table $T_l$ created for $l$-th element in the schema,
- $q$ is the number of all elements in the schema,
- $f_Q(R, D_{\text{sample}})$ is a query-cost function, where $S_i$ is cost and $P_{S_i}$ is probability of $i$-th given select query and $J_k$ is cost and $P_{J_k}$ is probability of $k$-th given join query,
- $m$ is the number of select queries in $D_{\text{sample}}$, and
- $n$ is the number of join queries in $D_{\text{sample}}$.

In other words $f_M(R, D_{\text{sample}})$ represents the total memory cost of the mapping instance, whereas $f_Q(R, D_{\text{sample}})$ represents the total query cost. The probabilities $P_{S_i}$ and $P_{J_k}$ enable to specify which elements will (not) be often retrieved and which sets of elements will (not) be often combined to search.

As we can see, this algorithm represents another way of finding a reasonable suboptimal solution in the theoretically infinite set of possibilities – using (in this case two) terminal conditions.

4) A Hill Climbing Algorithm: The last but not least cost-driven adaptable representative can be found in paper [23]. The approach is again based on a greedy type of algorithm, in this case a Hill climbing strategy that is depicted by Algorithm 3.

**Algorithm 3 Hill Climbing Algorithm**

**Input:** $S_{\text{init}}$, $T$, $f_{\text{map}}$, $D_{\text{sample}}$, $f_{\text{cost}}$

**Output:** $R_{\text{opt}}$

1: $S_{\text{opt}} \leftarrow S_{\text{init}}$
2: $R_{\text{opt}} \leftarrow f_{\text{map}}(S_{\text{opt}})$
3: $\text{cost}_{\text{opt}} \leftarrow f_{\text{cost}}(R_{\text{opt}}, D_{\text{sample}})$
4: $T_{\text{tmp}} \leftarrow T$
5: while $T_{\text{tmp}} \neq \emptyset$ do
6: \hspace{1em} $t \leftarrow$ any member of $T_{\text{tmp}}$
7: \hspace{1em} $T_{\text{tmp}} \leftarrow T_{\text{tmp}} \setminus \{t\}$
8: \hspace{1em} $S_{\text{tmp}} \leftarrow t(S_{\text{opt}})$
9: \hspace{1em} $\text{cost}_{\text{tmp}} \leftarrow f_{\text{cost}}(f_{\text{map}}(S_{\text{tmp}}), D_{\text{sample}})$
10: \hspace{1em} if $\text{cost}_{\text{tmp}} < \text{cost}_{\text{opt}}$ then
11: \hspace{2em} $S_{\text{opt}} \leftarrow S_{\text{tmp}}$
12: \hspace{2em} $R_{\text{opt}} \leftarrow f_{\text{map}}(S_{\text{opt}})$
13: \hspace{2em} $\text{cost}_{\text{opt}} \leftarrow \text{cost}_{\text{tmp}}$
14: \hspace{1em} $T_{\text{tmp}} \leftarrow T$
15: end if
16: end while
17: return $R_{\text{opt}}$

As we can see, the hill climbing strategy differs from the simple greedy strategy depicted in Algorithm 2 in the way it chooses the appropriate transformation $t \in T$. In the previous case the least expensive transformation that can reduce the current (sub)optimum is chosen, in this case it is the first such transformation found.

The schema transformations are based on the idea of vertical (V) or horizontal (H) cutting and merging the given XML schema fragment(s). The set $T$ consists of the following four types of (pairwise inverse) operations:

- $V$-Cut($f$, $(u,v)$) – cuts fragment $f$ into fragments $f_1$ and $f_2$, s.t. $f_1 \cup f_2 = f$, where $(u, v)$ is an edge from $f_1$ to $f_2$, i.e. $u \in f_1$ and $v \notin f_2$
- $V$-Merge($f_1$, $f_2$) – merges fragments $f_1$ and $f_2$ into fragment $f = f_1 \cup f_2$
- $H$-Cut($f$, $(u, v)$) – splits fragment $f$ into twin fragments $f_1$ and $f_2$ horizontally from edge $(u, v)$, where $u \notin f$ and $v \in f$, s.t. $\text{ext}(f_1) \cap \text{ext}(f_2) = \emptyset$ 6

6.$\text{ext}(f_i)$ is the set of all document-instance fragments conforming to the schema fragment $f_i$.

7.$\text{ext}(f_1)$ and $\text{ext}(f_2)$ are called twins if $\text{ext}(f_1) \cap \text{ext}(f_2) = \emptyset$ and for each node $u \in f_1$, there is a node $v \in f_2$ with the same label and vice versa.
• **H-Merge** \(f_1, f_2\) – merges two twin fragments \(f_1\) and \(f_2\) into one fragment \(f\) s.t. \(\text{ext}(f_1) \cup \text{ext}(f_2) = \text{ext}(f)\)

As we can observe, V-Cut and V-Merge operations are similar to outlining and inlining of the fragment \(f_2\) out of or into the fragment \(f_1\). On the other hand, H-Cut operation, which is in practice applied only on shared fragments, corresponds to splitting of elements mentioned in LegoDB mapping, i.e. duplication of the shared part. Likewise the H-Merge operation corresponds to inverse merging of elements.

The fixed XML-to-relational mapping maps each fragment \(f_i\) which consists of nodes \(\{v_1, v_2, ..., v_n\}\) to relation \(R_i = (id(r_i) : \text{int}, id(r_i, \text{parent}) : \text{int}, \text{lab}(v_1) : \text{type}(v_1),..., \text{lab}(v_n) : \text{type}(v_n))\) where \(r_i\) is the root element of \(f_i\). Note that such mapping is again similar to locally applied Universal table.

The cost function \(f_{cost}(R, D_{sample})\) is expressed as

\[
f_{cost}(R, D_{sample}) = \sum_{i=1}^{n} w_i \ast \text{cost}(Q_i, R)
\]

where \(D_{sample}\) consists of a sample set of XML documents and a given query workload \(\{(Q_i, w_i)_{i=1,2,...,n}\}\), where \(Q_i\) is an XML query and \(w_i\) is its weight. The cost function \(\text{cost}(Q_i, R)\) for a query \(Q_i\) which accesses fragment set \(\{f_{i1}, ..., f_{im}\}\) is expressed as

\[
\text{cost}(Q_i, R) = \sum_{j,k} |f_{ij}| \ast \text{Sel}_{ij} + \delta \ast (|E_{ij}| + |E_{ik}|)/2
\]

where \(f_{ij}\) and \(f_{ik}\), \(j \neq k\) are two join fragments, \(|E_{ij}|\) is the number of elements in \(\text{ext}(f_{ij})\), and \(\text{Sel}_{ij}\) is the selectivity of the path from the root to \(f_{ij}\) estimated using Markov table. In other words, the formula simulates the cost for joining relations corresponding to fragments \(f_{ij}\) and \(f_{ik}\).

The authors further analyze the influence of the choice of initial schema \(S_{init}\) on efficiency of the search algorithm. They analyze three types of initial schema decompositions leading to Binary [6], Shared, or Hybrid [9] mapping. The paper concludes with the finding that a good choice of an initial schema is crucial and can lead to faster searches of the suboptimal mapping.

### B. User-Driven Techniques

As mentioned above, the most flexible approach is “to leave the whole process in hands of a user” who defines both the target database schema and the required mapping. We speak about so-called user-defined mapping techniques. Probably due to simple implementation they are especially popular and supported in most commercial database systems.\(^8\)

At first sight the idea is correct – users can decide what suits them most and are not restricted by features and especially disadvantages of a particular technique. The problem is that such approach assumes users skilled in two complex technologies – (object-)relational databases and XML. Furthermore, for more complex applications the design of an optimal relational schema is generally an uneasy task.

On this account several new techniques – for the purpose of this paper called user-driven mapping strategies – were proposed. The main difference is that the user can influence a default fixed mapping strategy using annotations which specify the required mapping for particular schema fragments. The set of allowed mappings is naturally limited but still enough powerful to define various mapping strategies.

Each of the techniques is characterized by the following four features:

- an initial XML schema \(S_{init}\),
- a set of allowed fixed XML-to-relational mappings \(\{f_{map}\}_{i=1,...,n}\),
- a set of annotations \(A\), each of which is specified by name, target, allowed values, and function, and
- a default mapping strategy \(f_{def}\) for not annotated fragments.

1) **MDF**: Probably the first approach which faces the mentioned issues is proposed in papers [24] [31] (which extend ideas of papers [19] [32]) as ShreX or Mapping definition framework (MDF). It allows users to specify the required mapping and it is able to check correctness and completeness of such specifications and to complete possible incompleteness. The mapping specifications are made by annotating the input XSD with a predefined set of annotations, i.e. attributes from namespace called mdf. The set of annotating attributes \(A\) is listed in Table 1.

As we can see from the table, the set of allowed XML-to-relational mappings \(\{f_{map}\}_{i=1,...,n}\) involves inlining and outlining of an element or an attribute. Edge mapping [6] strategy, and mapping an element or an attribute to a CLOB column. Furthermore, it enables to specify the required capturing of the structure of the whole schema using one of the following three approaches:

- **Key, Foreign Key, and Ordinal Strategy (KFO)** – each node is assigned a unique integer ID and a foreign key pointing to parent ID, the sibling order is captured using an ordinal value
- **Interval Encoding** – a unique \(\{\text{start}, \text{end}\}\) interval is assigned to each node corresponding to preorder and postorder traversal entering time
- **Dewey Decimal Classification** – each node is assigned a path to the root node described using concatenation of node IDs along the path

As side effects can be considered attributes for specifying names of tables or columns and data types of columns. Not annotated parts are stored using user-predefined rules, whereas such mapping is always a fixed one.

2) **XCacheDB System**: Paper [25] also proposes a user-driven mapping strategy which is implemented and experimentally tested as an XCacheDB system. Similarly to the previous case a user can provide an annotated XML schema which contains the demanded mappings for particular schema fragments, otherwise a default strategy is used. Unfortunately the system considers only unordered and acyclic XML schemes and omits mixed-content elements.

\(^8\) An overview and analysis of commercial user-defined approaches can be found in [19].
The set of annotating attributes \( A \) that can be assigned to any node \( v \in S_{\text{init}} \) is listed in Table II. As we can see, it enables inlining and outlining of a node, storing a fragment into a BLOB column, specifying table names or column names, and specifying column data types. The main difference is in the data redundancy allowed by attribute \( \text{STORE}_\text{BLOB} \) which enables to shred the data into table(s) and at the same time to store pre-parsed XML fragments into a BLOB column.

The fixed mapping uses a slightly different strategy: Each element or attribute node is assigned a unique ID. Each fragment \( f \) is mapped to a table \( T_f \) which has an attribute \( a_{vID} \) of ID data type for each element or attribute node \( v \in f \). If \( v \) is an atomic node\(^9\), \( T_f \) has also an attribute \( a_v \) of the same data type as \( v \). For each distinct path that leads to \( f \) from a repeatable ancestor \( v \), \( T_f \) has a parent reference column of ID type which points to ID of \( v \). Note that this mapping strategy is again a fixed one.

For better lucidity we recapitulate the main features of the mentioned cost-driven and user-driven approaches in Tables III and IV respectively.

### C. Theoretic Issues

Besides proposals of cost-driven and user-driven techniques there are also papers which discuss the corresponding open issues of various XML-to-relational mappings and their efficiency on theoretic level.

### Table I

**Annotation Attributes for MDF**

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Target</th>
<th>Value</th>
<th>Function</th>
</tr>
</thead>
<tbody>
<tr>
<td>outline</td>
<td>attribute or element</td>
<td>true, false</td>
<td>If the value is true, a separate table is created for the attribute / element. Otherwise, it is inlined to parent table.</td>
</tr>
<tr>
<td>tablename</td>
<td>attribute, element, or group</td>
<td>string</td>
<td>The string is used as the table name.</td>
</tr>
<tr>
<td>columnname</td>
<td>attribute, element, or simple type</td>
<td>string</td>
<td>The string is used as the column name.</td>
</tr>
<tr>
<td>sqltype</td>
<td>attribute, element, or simple type</td>
<td>string</td>
<td>The string defines the SQL type of a column.</td>
</tr>
<tr>
<td>structurescheme</td>
<td>root element</td>
<td>KFO, Interval, Dewey</td>
<td>Defines the way of capturing the structure of the whole schema.</td>
</tr>
<tr>
<td>edgemapping</td>
<td>element</td>
<td>true, false</td>
<td>If the value is true, the element and all its subelements are mapped using Edge mapping.</td>
</tr>
<tr>
<td>maptoclob</td>
<td>attribute or element</td>
<td>true, false</td>
<td>If the value is true, the element / attribute is mapped to a CLOB column.</td>
</tr>
</tbody>
</table>

### Table II

**Annotation Attributes for XCacdeDB**

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Value</th>
<th>Function</th>
</tr>
</thead>
<tbody>
<tr>
<td>INLINE</td>
<td>( \emptyset )</td>
<td>If placed on a node ( v ), the fragment rooted at ( v ) is inlined into parent table.</td>
</tr>
<tr>
<td>TABLE</td>
<td>( \emptyset )</td>
<td>If placed on a node ( v ), a new table is created for the fragment rooted at ( v ).</td>
</tr>
<tr>
<td>STORE_BLOB</td>
<td>( \emptyset )</td>
<td>If placed on a node ( v ), the fragment rooted at ( v ) is stored also into a BLOB column.</td>
</tr>
<tr>
<td>BLOB_ONLY</td>
<td>( \emptyset )</td>
<td>If placed on a node ( v ), the fragment rooted at ( v ) is stored into a BLOB column.</td>
</tr>
<tr>
<td>RENAME</td>
<td>string</td>
<td>The value specifies the name of corresponding table or column created for node ( v ).</td>
</tr>
<tr>
<td>DATATYPE</td>
<td>string</td>
<td>The value specifies the data type of corresponding column created for node ( v ).</td>
</tr>
</tbody>
</table>

#### 1) Data Redundancy

As mentioned above, the XCacheDB system allows a certain degree of redundancy to ensure more efficient query processing. The corresponding paper [25] discusses the strategy also on theoretic level. There are two main representatives of the allowed redundancy – BLOB columns and the violation of BCNF or 3NF condition. On this account the authors define four classes of XML schema decompositions.

Before we state the definitions we have to note that this approach is based on a slightly different graph representation of a schema than was defined by Definition 5. In this case nodes of the graph correspond to elements, attributes, or pc-data, whereas edges are labelled with corresponding operators.

**Definition 8:** A schema decomposition is minimal if all edges connecting nodes of different fragments are labelled with “*” or “+”.

**Definition 9:** A schema decomposition is 4NF if all fragments are 4NF fragments. A fragment is 4NF if no two nodes of the fragment are connected by a “*” or “+” labelled edge.

**Definition 10:** A schema decomposition is non-MVD if all fragments are non-MVD fragments. A fragment is non-MVD if all “*” or “+” labelled edges appear in a single path.

**Definition 11:** A schema decomposition is inlined if it is non-MVD but it is not a 4NF decomposition. A fragment is inlined if it is non-MVD but it is not a 4NF fragment.

According to these definitions fixed mapping strategies (e.g. [9] [10]) naturally consider only 4NF decompositions which are least space-consuming and seem to be the best choice if we do not consider any other information. Paper [25] shows that having further information (in this particular case given by a user), the choice of other type of decomposition

---

\(^9\)An attribute node or an element node having no subelements.
can lead to more efficient query processing though it requires a certain level of redundancy.

2) Grouping problem: Paper [28] is dealing with the idea that searching a (sub)optimal relational decomposition is not only related to given XML schema, query workload, and XML data, but it is also highly influenced by the chosen query translation algorithm\(^\text{10}\) and the cost model.

For the theoretic purpose a subset of the problem – so-called grouping problem – is considered. It deals with possible storage strategies for shared subelements, i.e. either into one common table (so-called fully grouped strategy) or into separate tables, one for each sharer (so-called fully partitioned strategy). For analysis of its complexity the authors further define two simple cost metrics:

- RelCount – the cost of a relational query is the number of relation instances in the query expression
- RelSize – the cost of a relational query is the sum of the number of tuples in relation instances in the query expression

and three query translation algorithms:

- Naive Translation – performs a join between the relations corresponding to all the elements appearing in the query,
- Hill Climbing
- LegoDB

\(^\text{10}\)An algorithm for translating XML queries into SQL queries

A query containing “/” or “/*” operators.

\(^\text{11}\)A wild-card query is converted into union of several queries, one for each satisfying wild-card substitution

- Single Scan – a separate relational query is issued for each leaf element and joins all relations on the path until the least common ancestor of all the leaf elements is reached
- Multiple Scan – on each relation containing a part of the result is applied Single Scan algorithm and the resulting query consists of union of the partial queries

On a simple example the authors show that for a wild-card query \(Q\) which retrieves a shared fragment \(f\) with algorithm Naive Translation the fully partitioned strategy performs better, whereas with algorithm Multiple Scan the fully grouped strategy performs better. Furthermore, they illustrate that reliability of the chosen cost model is also closely related to query translation strategy. If a query contains not very selective predicate the optimizer may choose an index lookup which retrieves a shared fragment \(f\) with algorithm Naive Translation the fully partitioned strategy performs better, whereas with algorithm Multiple Scan the fully grouped strategy performs better. Furthermore, they illustrate that reliability of the chosen cost model is also closely related to query translation strategy. If a query contains not very selective predicate the optimizer may choose an index lookup

Last but not least the authors theoretically prove that various combinations of the above mentioned cost metrics and translation algorithms can produce differently complex problems,
up to NP-hard ones.

IV. SUMMARY

We can sum up the state of the art of adaptability of database-based XML-processing methods into the following natural but important findings:

1) As the storage strategy has a crucial impact on query-processing performance, a fixed mapping based on predefined rules and heuristics is not universally efficient.
2) It is not an easy task to choose an optimal mapping strategy for a particular application and thus it is not advisable to rely only on user's experience and intuition.
3) As the space of possible XML-to-relational mappings is very large (usually theoretically infinite) and most of the subproblems are even NP-hard, the exhaustive search is impractical and often even impossible. It is necessary to define search heuristics, approximation algorithms, and/or reliable terminal conditions.
4) The choice of an initial schema can strongly influence the efficiency of the search algorithm. It is reasonable to start with at least "locally good" schema.
5) A strategy of finding a (sub)optimal XML schema should take into account not only the given schema, query workload, and XML data statistics, but also consider possible query translations, cost metrics, and their consequences.
6) Cost evaluation of a particular XML-to-relational mapping should not involve time-consuming construction of a particular relational schema, loading sample XML data and analyzing the resulting relational structures. It can be optimized using cost estimation of XML queries, XML data statistics, etc.
7) Despite the previous claim, the user should be allowed to influence the mapping strategy. On the other hand, the approach should not demand a full schema specification but it should be able to efficiently complete the user-given hints.
8) Even thought a storage strategy is able to adapt to a given sample of schemes, data, queries, etc., its efficiency is still endangered by later changes of the expected usage.

V. OPEN ISSUES

Although each of the existing approaches brings certain interesting ideas and optimizations, there is still a space of possible future improvements of the adaptable methods. We describe and discuss them in this section starting from (in our opinion) the least complex ones.

A. Problem of Missing Input Data

As we already know, for cost-driven techniques there are three types of input data:

- an XML schema $S_{init}$,
- a set of XML documents $\{d_1, d_2, ..., d_k\}$ valid against $S_{init}$, and
- a set of XML queries $\{q_1, q_2, ..., q_l\}$ over $S_{init}$ (eventually with corresponding weights).

The problem of missing input XML schema $S_{init}$ was already outlined in the introduction in connection with advantages and disadvantages of generic and schema-driven methods. As we suppose that the adaptability is the ability to adapt to the given situation, an adaptive method which does not depend on existence of an XML schema but can exploit the information if being given is probably a natural first type of improvement. This idea is also strongly related to the earlier mentioned problem of choice of a locally good initial schema $S_{init}$. The corresponding main questions are:

- Can be the user-given schema considered as a good candidate for initial schema $S_{init}$?
- How can we measure this quality?
- How can we (efficiently) find an eventual better candidate?
- Can we find such candidate for schema-less XML documents?

A possible solution can be found in exploitation of methods for automatic construction of XML schema for the given set of XML documents (e.g. [33] [34]). These methods are able to derive corresponding content models from a given sample set of (similar) XML documents. Thus if we assume that documents are more precise sources of structural information, we can expect that a schema generated on their bases will have good characteristics too.

On the other hand, the problem of missing input XML documents can be at least partly solved using reasonable default settings based on general analysis of real XML data (e.g. [13] [14]). Furthermore, the surveys show that real XML data are surprisingly simple thus the default mapping strategy does not have to be complex too. It should rather focus on efficient processing of frequently used XML patterns.

On the contrary, the presence of sample query workload is crucial since (to our knowledge) there are no analyses on real XML queries, i.e. no source of information for default settings. The reason is that the way how to collect such real representatives is not as straightforward as in case of XML documents which can be easily crawled from the Internet. Currently the best sources of XML queries are XML benchmarking projects (e.g. [35] [36]) but as the data and especially queries are supposed to be used for rating the performance of a system in various situations, they cannot be considered as an example of a real workload.

Naturally, the query statistics can be gathered by the system itself and the relational schema can be adapted continuously. But this is already the problem of dynamic adaptability discussed later in Section V-E.

B. Efficient Solution of Subproblems

A surprising fact we have encountered are numerous simplifications of the chosen solutions. As it was mentioned, some of the techniques omit, e.g., ordering of elements, mixed contents, or recursion. This is a bit confusing finding regarding the fact that there are proposals of efficient processing of these XML constructs (e.g. [37]) and that adaptive methods should be able to cope with various situations.
A similar observation can be done for user-driven methods. Though the proposed systems are able to store schema fragments in various ways, the default mapping strategy for not annotated parts of a given schema is again a fixed one. It seems to be an interesting optimization to join the ideas of cost-driven and user-driven approaches and to search the (sub)optimal mapping for not annotated parts using a cost-driven method.

C. Deeper Exploitation of User-Given Information

Another open issue is the problem of possible deeper exploitation of the information given by the user. We can identify two main questions:

1) How can be the user-given information better exploited?
2) Are there any other information a user can provide to increase the efficiency?

A possible answer at least for the first question can be found in the idea of pattern matching. The idea is to use user-given schema annotations as “hints” how to store particular XML patterns which can be further exploited in searching an efficient mapping for not annotated parts. We can naturally predict that structurally similar fragments should be stored similarly and thus to focus on finding these fragments in the rest of the schema. The main problem of this idea is how to identify the structurally similar fragments. If we consider the variety of XML-to-XML transformations, two structurally same fragments can be expressed using “at first glance” different regular expressions. Thus it is necessary to propose particular levels of equality of XML schema fragments and algorithms how to determine them. Last but not least, such system should focus on scalability of the similarity metric and particularly its reasonable default setting (based on existing analyses of real-world data).

D. Theoretical Analysis of the Problem

As we can see from the overview of the existing methods, there are various types of XML-to-XML transformations, whereas the mentioned ones certainly do not cover the whole set of possibilities. Unfortunately there seems to be no theoretic study of these transformations, their key characteristics, and possible classifications. The study can, among others, focus on equivalent and generalizing transformations and as such serve as a good basis for the pattern matching strategy.

Especially interesting will be the question of NP-hardness in connection with the set of allowed transformations and its complexity (similarly to paper [28] which analyzes theoretical complexity of combinations of cost metrics and query translation algorithms). Such survey will provide useful information especially for optimizations of the search algorithm.

E. Dynamic Adaptability

The last but not least mentioned open issue is naturally connected with the most striking disadvantage of adaptive methods – the problem of possible changes of both XML queries and XML data that can lead to crucial worsening of their efficiency. As it was already mentioned, it is also related to the problem of missing input XML queries and ways how to gather them. Furthermore, the question of changes of XML data opens another wide research area of updatability of the stored data – a feature that is often omitted in current approaches although its importance is crucial.

The solution to these issues – i.e. a system that is able to adapt dynamically – is obvious and challenging but it is not an easy task. It should especially avoid total reconstructions of the whole relational schema and corresponding necessary reinserting of all the stored data, or such operation should be done only in very special cases and not often.

On the other hand, this “brute-force” approach can serve as a good inspiration. It is possible to suppose that changes especially in case of XML queries will not be radical but will have a gradual progress. Thus the changes of the relational schema will be mostly local and we can apply the expensive reconstruction just locally. Furthermore, we can again exploit the idea of pattern matching and try to find the XML pattern defined by the modified schema fragment in the rest of the schema.

Another question is how often should be the relational schema reconstructed. The natural idea is of course “not too often”. But, on the other hand, a research can be done on the idea of performing gradual minor changes. It is probable that such approach will lead to less expensive (in terms of reconstruction) and at the same time more efficient (in terms of query processing) system. The former hypothesis should be verified, the latter one can be almost certainly expected. The key issue is how to find a reasonable compromise.

VI. Conclusion

The main goal of this paper was to describe and discuss the current state of the art and open issues of adaptability in database-based XML-processing methods. First of all, we have stated the reasons why this topic should be ever studied. Then we have provided an overview and classification of the existing approaches and their features and summed up the key findings. Finally, we have discussed the corresponding open issues and their possible solutions.

Our aim was to show that the idea of processing XML data using relational databases is still up to date and should be further developed. From the overview of the state of the art we can see that even though there are interesting and inspiring approaches, there is still a variety of open problems which can further improve the database-based XML processing.

Our future work will naturally follow the open issues stated at the end of this paper and especially survey into the possible solutions we have mentioned. Firstly, we will focus on the idea of improving the user-driven techniques using adaptive algorithm for not annotated parts of the schema together with deeper exploitation of the user-driven hints using pattern-matching methods – i.e. a hybrid user-driven cost-based system. Secondly, we will deal with the problem of missing theoretic study of schema transformations, their classification, and particularly influence on the complexity of the search algorithm. Finally, on the basis of the theoretical study and the hybrid system we will study and experimentally analyze the dynamic enhancing of the system.
It is important to mention that though all the open issues can be studied from various points of view, they are still closely related and influence each other. Thus it is always important to consider the given problem globally and not omit important consequences.
